Abstract. We investigate the possibility that patches of old radio plasma (‘radio ghosts’) of former radio galaxies form a second distinct phase of the inter-galactic medium (IGM), not mixed with the thermal gas. The separation of this phase from the ambient gas and its resistance against eroding turbulent forces is given by magnetic fields, which are expected to be roughly in pressure equilibrium with the surrounding medium. Since patches of this plasma are largely invisible in the radio we use the term ‘radio ghost’ to characterize their nature. Possibilities and difficulties of different detection strategies of ghosts are discussed. These involve radio emission, cosmic microwave background (CMB) and starlight Comptonization, and Faraday rotation. Re-activation of the electron population in shock waves of cosmological structure formation, which seems to lead to the cluster radio relic phenomena. We discuss the role radio ghosts can have: They are able to store relativistic particles for cosmological times, but are also able to release them under the influence of very strong turbulence. This might happen during a major merger event of clusters of galaxies. The released relativistic proton population could produce the observed radio halos of some cluster of galaxies via hadronic reactions with the background gas leading to the production of secondary electrons and positrons.

Destroyed ghosts, mixed with the IGM can help to magnetize it. Finally, the strong field strength within ghosts should have a significant impact on the propagation of extragalactic high energy cosmic rays.

1. Introduction

Active radio galaxies fill large volumes in the IGM with radio plasma. Over cosmological time-scales this plasma becomes rapidly invisible to radio telescopes due to inverse Compton (IC) and synchrotron energy losses of the relativistic electrons. Afterwards it might form an invisible, but possibly important phase of the IGM. The amount of energy stored in this form in the IGM is difficult to estimate. Various approaches have been made, depending on different assumptions, but giving comparable results

(Enßlin et al. 1997, 1998a). The simplest is to assume that the power of active galactic nuclei deposited into radio plasma and into X-ray light output are comparable. The integrated energy density (per co-moving volume) in quasar light emitted during (and estimated for) the epoch of quasar activity is $(0.9 - 1.3) \cdot 10^{-15} \text{ erg cm}^{-3}$ (Chokshi & Turner 1992). The energy density of the radio plasma should be the same, if our assumption holds. For comparison: if this energy were to be thermalized and transferred to the gas in the Universe, it would give a heat input of $kT = (1.3 - 1.9) \text{ keV } (\Omega_b h_{50}^2 / 0.05)^{-1}$ at $z \approx 2$ (assuming here and in the following $H_0 = 50 h_{50} \text{ km s}^{-1} \text{ Mpc}^{-1}$).

But we argue that this does not necessarily happen. The radio plasma and later radio ghosts will expand or contract until they reach pressure equilibrium with the surrounding medium. The pressure of the ghost is given by that of the confined relativistic particles and the magnetic fields, assumed to be in rough energy equipartition. Therefore magnetic fields should be typically of the strength of the thermal energy density of the environment. Subsonic turbulence in this environment, which has an energy density below the thermal energy density, is therefore not strong enough to overcome the magnetic elastic forces of the radio ghost. Sonic or super-sonic turbulence, which is e.g. expected in giant merger events of cluster of galaxies, can ‘shred’ the ghost into smaller pieces. The size of such pieces will be comparable to the eddy size of the turbulence. This means, since a typical turbulent spectrum has less energy density on smaller scales, that there is a length-scale below which the turbulence is not able to overcome magnetic forces. Turbulent erosion of radio ghosts should stop at this length-scale, leaving small-scale patches of still unmixed old radio plasma.

2. Detection of Radio Ghosts

The number density, sizes, and filling-factor of our hypothesized radio ghosts is poorly constrained due to the uncertainties in the above considerations. But this knowledge would be required in order to estimate their influence on the properties of the IGM. Observational evidence of their existence and measurements of their properties

would therefore be of great value. But as we show in the following, this is hard to achieve, justifying the name ‘radio ghosts’.

2.1. Synchrotron Emission

The old population of relativistic electrons within the ghost is emitting low frequency radio emission. At a given frequency ν synchrotron emission reveals mostly electrons with a Lorentz-factor of

$$\gamma(\nu, B, z) = \sqrt{2\pi m_e c \nu (1+z) / (3eB)}, \quad (1)$$

where B is the magnetic field strength and z the redshift of the emission region. Electrons will cool due to synchrotron and IC losses with a cooling time of

$$t_{\text{cool}}(\gamma, B, z) = \left(\frac{4}{3} \frac{\sigma_T}{m_e c} (\varepsilon_B + \varepsilon_{\text{CMB}}) \gamma \right)^{-1}, \quad (2)$$

where $\varepsilon_B = B^2/(8\pi)$ and $\varepsilon_{\text{CMB}} = \varepsilon_{\text{CMB},o}(1+z)^4$ are the magnetic field and CMB energy density, the latter expressed by its present day value $\varepsilon_{\text{CMB},o}$. The cooling time of electrons visible at a frequency ν is $t_{\text{cool}}(\gamma(\nu, B, z), B, z)$. This function has a maximum at $\varepsilon_B = \varepsilon_{\text{CMB}}/3$ for fixed ν and z . Therefore any electron visible at a given frequency ν had to be accelerated no later than

$$t_{\text{cool,max}}(\nu, z) = 0.7 \text{ Gyr } (\nu/100 \text{ MHz})^{-1/2} (1+z)^{-7/2} \quad (3)$$

ago, otherwise it could not have retained its energy. This is an upper limit, and in reality the lifetime of radio visible electrons is always shorter: if the magnetic fields are strong ($\varepsilon_B > \varepsilon_{\text{CMB}}/3$) synchrotron cooling is stronger, if the magnetic fields are weak ($\varepsilon_B < \varepsilon_{\text{CMB}}/3$) high energy electrons are visible at the observing frequency ν which also have shorter IC-cooling times than given by Eq. 3. Thus, low frequency radio observation cannot reveal ghosts which are older than about a Gyr, unless the electron population has been recently re-accelerated.

2.2. CMB Comptonization

The relativistic electrons, if still present within ghosts, will scatter the CMB photons to higher energies. Since the infrared and the optical bands are overwhelmed by other sources, the chance of detection only exists above the UV range. In order to have a typical energy of 10 eV for a scattered CMB photon $\gamma \approx 100$ is required, since $< \varepsilon_{\text{IC}} > = \frac{4}{3} \gamma^2 2.7 k T_{\text{CMB}}$ (Blumenthal & Gould 1970). Thus, it has to be examined if energetic electrons can maintain an energy of 50 MeV for cosmological times.

Again we want to examine the most optimistic case in order to demonstrate the difficulties of the detection of ghosts. The minimal cooling is given by the effect of

CMB-IC cooling alone. Pure CMB-IC-cooling of electrons is governed by

$$\frac{d\gamma}{dt} = -\frac{\gamma}{t_{\text{cool}}(\gamma, 0, z)} = -a_{\text{IC},o} \gamma^2 (1+z)^4, \quad (4)$$

with $a_{\text{IC},o} = \frac{4}{3} \sigma_T \varepsilon_{\text{CMB},o} / (m_e c)$. Assuming for simplicity an Einstein-de-Sitter Universe¹ one finds that for an arbitrary high injection energy at z_{inj} every electron has cooled below

$$\gamma_{\text{max}} = \frac{5 H_o}{2 a_{\text{IC},o}} \frac{1}{(1+z_{\text{inj}})^{5/2} - 1} \approx \frac{48 h_{50}}{(1+z_{\text{inj}})^{5/2} - 1}. \quad (5)$$

In order to get IC scattered CMB photons above 10 eV the last acceleration of the electron population must have been no later than $z_{\text{inj}} = 0.16$, corresponding to an age of 4 Gyr. It is therefore impossible to detect old radio ghosts from the cosmic epoch of violent quasar activity around $z \approx 1...3$ by their IC-flux. Synchrotron and other losses, which we neglected here, make the detection only more difficult.

Another strategy might be to look for characteristic CMB decrements. The relative number of up-scattered CMB photons is given by the Thomson optical depth

$$\begin{aligned} \frac{\Delta I_{\text{CMB,ghost}}}{I_{\text{CMB}}} &= \tau_{\text{ghost}} = \sigma_T n_{e,\text{ghost}} l_{\text{ghost}} \\ &= 2 \cdot 10^{-6} \left(\frac{n_{e,\text{ghost}}}{10^{-5} \text{ cm}^{-3}} \right) \left(\frac{l_{\text{ghost}}}{100 \text{ kpc}} \right) \end{aligned} \quad (6)$$

A density of the relativistic electrons of $n_{e,\text{ghost}} = 10^{-5} \text{ cm}^{-3}$ is optimistic but might apply to ghosts confined in the dense ICM. Ghosts outside clusters of galaxies will have relativistic electron densities which are lower by orders of magnitude. Therefore the only chance to detect ghosts is inside clusters of galaxies. And there, due to their low optical depth, only a cluster averaged effect can produce a marginal detection: we assume that a small fraction Φ_{Vol} of the cluster volume is filled with this remnant radio plasma. Further we assume pressure equilibrium between the ghosts and the ICM, equipartition between magnetic fields and relativistic electrons inside the ghosts², and a typical relativistic electron energy of 1 MeV. For a 10 keV cluster this gives a ratio of ghost- to ICM-optical depth of

$$\frac{\tau_{\text{ghost}}}{\tau_{\text{ICM}}} \approx 0.03 \Phi_{\text{Vol}}, \quad (7)$$

determined by the ratio of relativistic to thermal electron number. Photons scattered by relativistic electrons are practically removed from the blackbody spectrum,

¹ The cosmic time is given by $t(z) = 2/(3 H_o)(1-(1+z)^{-3/2})$.

² This is again optimistic, since a substantial fraction of the relativistic particle pressure might be given by relativistic protons.

whereas thermal electrons are only shifted, leading to a decrement³ of

$$\frac{\Delta I_{\text{CMB,ICM}}}{I_{\text{CMB}}} \approx 0.06 \tau_{\text{ICM}}. \quad (8)$$

This implies that the relative strength of the ghost- and ICM-induced CMB decrements is

$$\frac{\Delta I_{\text{CMB,ghost}}}{\Delta I_{\text{CMB,ICM}}} \approx 0.5 \Phi_{\text{Vol}} \ll 1. \quad (9)$$

Ghosts are therefore hard to detect as a CMB decrement, but it can not be excluded that future instruments will see them, if our optimistic assumptions hold.

2.3. Starlight Comptonization

A low energy population of relativistic electrons, which may be present in radio ghosts, is able to scatter the starlight to higher energies. This was used as one possible scenario to explain the extreme ultraviolet (EUV) excess of the Coma cluster of galaxies (Enßlin et al. 1999). In this scenario the relativistic electrons must be located within magnetic fields which separate them from the dense ICM, otherwise high Coulomb losses would rapidly cool the electrons. This would be the case for an old electron population within radio ghosts. A difficulty of this scenario is the relatively high energy density required in the electron population to produce the detected EUV radiation. But if future observations with higher angular resolution show that the EUV excess is clumped around the cluster galaxies where the optical photon density is highest, this would be an indicator for IC scattering by a strong low energy electron population, which needs an environment as given within radio ghost.

2.4. Faraday Rotation

Magnetic fields in radio ghosts are expected to be in rough equipartition with the environment. Therefore one expects fields strengths of $0.1 \dots 1 \mu\text{G}$ for ghosts outside, and up to a few $10 \mu\text{G}$ for ghosts inside clusters of galaxies. Fields of such strength seem to be easily detectable at a first glance, since magnetic fields of μG strength were seen in clusters of galaxies by Faraday rotation measurements of linearly polarized background radio sources (for a review: Kronberg 1994). But Faraday rotation by radio ghosts should be very difficult to detect for two reasons: First, the electron number density is expected to be very low and Faraday rotation measures the product of magnetic fields strength times electron density. Second, the electrons are expected to be relativistic, and therefore Faraday rotation is suppressed (e.g. Jones & Hardee 1979).

³ This estimate is based on the maximal relative Sunyaev-Zeldovich decrement in flux at a frequency of $\nu \approx 1.8 kT_{\text{CMB}}/h$ and a cluster temperature of 10 keV. We used the non-relativistic Kompaneets approximation, which should be sufficiently accurate for an order of magnitude estimate.

Ghosts can only become detectable by Faraday rotation measurements, if the surrounding thermal gas is able to break into the ghost.

2.5. Cluster Radio Relics

Radio ghosts are practically invisible as long as their electron population remains at low energies. But if the population is re-accelerated the ghost becomes radio luminous again. This can happen when the ghost is dragged into a large-scale shock wave, e.g. in a merger event of clusters of galaxies or at the accretion shock where the matter is falling onto a cluster. The emission region is expected to be irregularly shaped, and should exhibit linear polarization due to the compression of the magnetic fields in the shock. Such regions are indeed observed at peripheral locations of a few clusters of galaxies and are called ‘cluster radio relics’. Their properties, such as degree and direction of polarization, surface luminosity, peripheral position etc., can be understood within such a scenario (Enßlin et al. 1998b). The observed rarity of the cluster radio relic phenomena can be understood in this context: the presence of a shock wave, which should be quite frequently found in and at clusters of galaxies, is not sufficient to produce a cluster radio relic, a radio ghost has to be present at the same location, too.

Therefore cluster radio relics are up to now the best signature of the existence of radio ghosts. On the other hand, radio ghosts seem to be sensitive tracers of large-scale shock waves and allow the study of cosmological structure formation in action.

3. The Possible Roles of Radio Ghosts

3.1. Storage Sites of Relativistic Protons

Radio ghosts consist of magnetic fields and low energy relativistic electrons. A long outstanding question is the extent to which radio plasma clouds contain relativistic protons. The detection of TeV γ -rays from blazars support the presence of a significant proton component, since this emission is difficult to understand within pure leptonic jet models (Mannheim 1998).

A relativistic proton population can therefore be expected within ghosts, since the escape of protons is suppressed due to the low cross field diffusion coefficient. In order to get an idea of the relevant diffusion time-scales we adopt a simplified version of the compound diffusion described in Duffy et al. (1995). We estimate the escape time of a 10 GeV proton in a $10 \mu\text{G}$ field, which could be typical for a ghost in a cluster environment. The parallel and cross-field diffusion coefficients

$$\kappa_{\parallel} \approx \frac{1}{3} c r_g / \delta_B(r_g) \quad (10)$$

$$\kappa_{\perp} \approx \frac{1}{3} c r_g \delta_B(r_g) \quad (11)$$

depend on the (relative) energy density in magnetic fluctuation $\delta_B(r_g) = \delta B^2(r_g)/B^2$ on the scale of the gyro-radius $r_g = 10^{-6}$ pc of the diffusing particle. The magnetic fields of the ghost are in rough equipartition with the surrounding thermal medium $\varepsilon_B \approx \varepsilon_{th}$. The level of turbulence on the turbulence injection scale $l_{inj} = 10$ kpc is assumed to be a small fraction of the thermal energy density. We adopt a value for the turbulence energy density integrated up to this scale: $\varepsilon_{turb}(l_{inj}) = 0.01 \varepsilon_{th}$. Assuming a Kolmogoroff turbulence spectrum, one gets a turbulent energy density integrated up to the scale r_g , of

$$\varepsilon_{turb}(r_g) = \varepsilon_{turb}(l_{inj}) (l_{inj}/r_g)^{-2/3} \approx 10^{-8.7} \varepsilon_{th}. \quad (12)$$

The turbulence-induced small-scale magnetic irregularities are therefore $\delta_B \approx 10^{-8.7}$, leading to a cross field diffusion coefficient of $\kappa_{\perp} \approx 10^{13.8} \text{ cm}^2 \text{ s}^{-1}$. This is far too small to allow any macroscopic diffusion.

But the high parallel diffusion coefficient of $\kappa_{\parallel} \approx 10^{31.2} \text{ cm}^2 \text{ s}^{-1}$ allows the particle to travel rapidly along the magnetic field lines. Now, if we allow neighboring field lines to diverge exponentially, a small diffusive step of the particle perpendicular to the field can be strongly amplified by the rapid movement along the field. This leads to the compound cross-field diffusion coefficient

$$\kappa_{comp} \approx \kappa_{\perp} (1 + \Lambda^2 / \ln \Lambda) \approx 10^{25.6} \text{ cm}^2 \text{ s}^{-1} \quad (13)$$

(Duffy et al. 1995), where the quantity

$$\Lambda = \frac{\delta_B(l_B)}{\sqrt{2} \delta_B(r_g)} \approx 10^{6.5} \quad (14)$$

is simplified here by assuming a single typical field correlation-length parallel and perpendicular to the field direction of $l_B \approx 10$ kpc. This is still too small to allow an efficient escape of protons from the ghost, since a typical diffusion time-scale is

$$\tau_{diff} \approx (10 \text{ kpc})^2 / (2 \kappa_{comp}) \approx 3 \cdot 10^{11} \text{ yr}. \quad (15)$$

On this argument, it seems reasonable that relativistic particles are confined for cosmological times within ghosts.

3.2. Escape of Relativistics Protons

Particles could escape if the diffusion coefficient is much higher. This could be the case for a higher turbulence level than assumed above. During a major cluster merger the turbulence can get into rough equipartition with the thermal energy density, thus being higher by two orders of magnitude than assumed above. If the turbulence is fully developed, the cross field diffusion coefficient $\kappa_{\perp}$ goes up by two orders of magnitude. Λ should remain constant, since it is mainly the ratio of large-scale to small-scale turbulent energy, which does not depend on the normalization of the turbulence energy spectrum. Therefore κ_{comp} increases also by a factor of 100, giving a diffusion time of 3 Gyr, which is still large.

But turbulence needs some time to develop fully from large injection scales to small dissipation scales. In a sudden merger the level of large-scale turbulence will increase for some time, whereas the small-scale turbulence is still low. The time-scale for a decay of a turbulent eddy of scale l with velocity v_{turb} is approximately the eddy-turnover time l/v_{turb} . A Kolmogoroff cascade needs therefore $\tau_{turb} \approx \frac{3}{2} l_{inj}/v_{turb}(l_{inj})$ to fully develop. Inserting $l_{inj} = 10$ kpc, and $v_{turb}(l_{inj}) = 1000$ km/s for strong turbulence in a galaxy cluster, one gets $\tau_{turb} \approx 15$ Myr.

During this period Λ can be increased by a factor of 100. This keeps $\kappa_{\perp}$ constant, but raises the compound diffusion coefficient by 4 orders of magnitude. The resulting escape time of $\tau_{diff} \approx 30$ Myr is comparable to τ_{turb} and allows therefore a large fraction of the confined protons to escape⁴. In this way a strong cluster merger event can lead to a sudden injection of relativistic protons into the dense ICM gas. The protons may stay for a cosmological time within the ICM, as simple diffusion-time estimates suggest (Enßlin et al. 1997; Berezhinsky et al. 1997).

3.3. Radio Halos

Cluster radio halos are rare occurrences, as are cluster radio relics. Their presence seem to be connected with a recent or on-going merger event of the cluster (De Young 1992), although there are many clusters showing evidence for strong merging there are very few radio halos observed.

The models for cluster radio halo formation can be divided into two groups: primary and secondary electron models, which also could be named leptonic and hadronic models. In leptonic models the radio emitting electrons are accelerated or injected into the ICM directly (Jaffe 1977; Rephaeli 1977, 1979; Roland 1981; Schlickeiser et al. 1987). In hadronic models (Dennison 1980) protons are accelerated or injected, and they interact hadronically with the ICM gas producing charged pions which decay into electrons and positrons mainly by the following reactions:

The same number of electrons and pions are produced, but since more π^+ than π^- are generated, and the decay of a π^+ gives more kinetic energy to the positron than the β -decay of a neutron to the electron, the secondary positron spectrum dominates over the secondary electrons at energies higher than the pion rest energy. If radio halos have

⁴ Both time-scales depend in a similar way on the chosen turbulence injection scale: $\tau_{diff} \sim l_{inj}^{2/3}$ and $\tau_{turb} \sim l_{inj}$. Therefore a probably larger l_{inj} increases the ratio of τ_{turb} and τ_{diff} , thus allowing more particles to escape within the period of strongly increased diffusion coefficient.

a hadronic origin, they are mainly synchrotron emission from positrons.

The advantage of the hadronic model of halo formation is that the lifetime of energetic protons in the ICM is of the order of a Hubble time (Enßlin et al. 1997), whereas radio emitting (at $\nu \approx \text{GHz}$) relativistic electrons cool in less than 0.2 Gyr (see Eq. 3). In the hadronic case this allows the protons to diffuse over the large observed radio emitting volume, even if they are released by point sources. In the leptonic models in-situ acceleration has to take place since the cooling time of the relativistic electrons is not sufficient to allow a travel distance to be comparable to the radio halo size. This makes acceleration in a cluster merger shock unlikely to be the explanation in the leptonic framework, since the shock crossing time is of the order of a Gyr, leading to a less symmetric emission profile than observed in clusters. On the other hand, in a hadronic model, where the protons are injected during the shock passage, the low interaction rate of the protons tend to smear out the effect of the time dependent shock passage and permit the cluster to remain radio luminous after the shocks disappeared. If radio halos are really connected to merger events, hadronic models are favored to explain their smooth observed profiles.

We thus propose that proton release from ghosts during a cluster merger event (Sec. 3.2) is an attractive injection mechanism for the hadronic halo formation scenario for several reasons. First it would explain the connection between merger events and radio halo formation. The protons are released in strong mergers only, because the diffusion coefficient depends strongly on the level of large-scale turbulence. Fermi acceleration in the turbulence or in cluster shocks may further energize this relativistic population. Note, that particle injection from a thermal distribution into a Fermi acceleration mechanism is ineffective, but proton release from ghosts would avoid this difficulty.

Simple shock acceleration models (without injection from ghosts) also predict a higher proton acceleration rate in strong mergers. But the rarity of cluster radio halos is difficult to understand in pure shock acceleration scenarios, since we know of several strong merging or post-merging clusters without a radio halo. A good example is Abell 3667, which shows evidence for a merger in X-rays (Markevitch et al. 1998), in the galaxy distribution, and by the existence of two radio relics (Röttgering et al. 1997). The morphology and location of these relics was recently modeled in a hydrodynamic simulation with simultaneous particle acceleration by Roettiger (1999). This cluster is apparently in a post-shock situation, comparable to Coma (Burns et al. 1995), but does not show any radio halo as Coma does.

The proposed ghost proton release scenario can give an explanation for this, since nearly all the relativistic protons should escape from the ghosts during one strong merger event. A second strong merger would not have the same effect, since there are no further protons to ‘release’

after the first strong merger event. If this is the explanation of the rarity of radio halos, it implies that many cluster might have had their halos in the past, and therefore many more radio halos should exist at higher redshifts than today.

3.4. Magnetization of the IGM

Magnetic tension should prevent the ghosts from being mixed with the IGM. But it is difficult to state to what level ghosts really can resist the turbulence, especially strong turbulence during major cluster merger event. If ghosts become mixed with the IGM, they release their relativistic particles⁵, and magnetize the thermal IGM gas. This can be a substantial source for the magnetic fields observed in clusters of galaxies. IGM magnetization by radio galaxies, which is a closely related idea, was proposed by Daly & Loeb (1990).

3.5. Propagation of Ultra-High Energy Cosmic Rays

It is widely believed that the origin of ultra-high energy cosmic rays (UHECRs) is extragalactic, since the galactic magnetic fields are not strong enough to confine them, so that a extremely strong and isotropically distributed population of galactic UHECR sources would be required to fit the flux and distribution of arrival directions.

The travel length L_{CR} of extragalactic UHECRs is of the order of a few 10 Mpc. It cannot be arbitrarily large for protons above the Greisen-Zatsepin-Kuzmin cutoff of $5 \cdot 10^{19}$ eV (Greisen 1966, Zatsepin & Kuzmin 1966) due to strong energy losses by photo-pion production in interactions with the CMB. Therefore the observed UHECRs are believed to be produced within the local supercluster (LSC). We want to examine the effect of a population of ghosts within the IGM of the LSC on the propagation of UHECRs. Note that we momentarily ignore any magnetic fields in the space between ghosts, which are extensively discussed in the literature (see e.g. Sigl et al. (1999), or Medina-Tanco (1998), and references therein).

We assume that a small fraction Φ_{Vol} of the volume of the LSC is filled with ghosts, which we assume to have a single, typical size of l_{ghost} . The number density of ghosts is therefore $n_{\text{ghost}} = \Phi_{\text{Vol}} l_{\text{ghost}}^{-3}$. The cross-section for an UHECR particle to hit a ghost is $\sigma_{\text{ghost}} = l_{\text{ghost}}^2$ leading to a mean free path of

$$L_{\text{ghost}} = \frac{1}{\sigma_{\text{ghost}} n_{\text{ghost}}} = 10 \text{ Mpc} \left(\frac{l_{\text{ghost}}}{0.1 \text{ Mpc}} \right) \left(\frac{\Phi_{\text{Vol}}}{0.01} \right)^{-1}.$$

Let us assume that a UHECR particle of energy E_{CR} entered a ghost. Its propagation direction will be deflected due to gyration in the magnetic fields. We assume that the magnetic fields are coherent on a scale l_{cell} , so that

⁵ If thermal gas is able to get into the strong magnetic fields of a ghost, relativistic particles can easily escape.

the typical change in direction during the passage through one coherence length is the angle

$$\alpha_{\text{cell}} = l_{\text{cell}}/r_g, \quad (16)$$

where

$$r_g = \frac{E_{\text{CR}}}{eB} = 0.1 \text{ Mpc} \left(\frac{E_{\text{CR}}}{10^{20} \text{ eV}} \right) \left(\frac{B}{\mu\text{G}} \right)^{-1} \quad (17)$$

is the gyro-radius of the particle. The accumulated angle change during the passage through the ghosts by $N_{\text{cell}} = l_{\text{ghost}}/l_{\text{cell}}$ regions of random field orientations is given by random walk arguments to be

$$\langle \alpha_{\text{ghost}}^2 \rangle = N_{\text{cell}} \alpha_{\text{cell}}^2 = l_{\text{ghost}} l_{\text{cell}}/r_g^2. \quad (18)$$

Isotropic scattering occurs if $\sqrt{\langle \alpha_{\text{ghost}}^2 \rangle} \geq \pi/2$, or equivalently

$$E_{\text{CR}} \leq E_* = 2 \cdot 10^{19} \text{ eV} \left(\frac{B}{\mu\text{G}} \right) \left(\frac{l_{\text{ghost}} l_{\text{cell}}}{0.1 \text{ Mpc} \times 0.01 \text{ Mpc}} \right)^{\frac{1}{2}}.$$

Particles above E_* experience only a small angle scattering during the passage through a ghost. The accumulated effect of several ghosts ($N_{\text{ghost}} = L_{\text{CR}}/L_{\text{ghost}}$) along the path of length L_{CR} of a UHECR is given by

$$\langle \alpha^2 \rangle = N_{\text{ghost}} \langle \alpha_{\text{ghost}}^2 \rangle = \Phi_{\text{Vol}} L_{\text{CR}} l_{\text{cell}}/r_g^2 \quad (19)$$

$$\sqrt{\langle \alpha^2 \rangle} = 18^\circ \left(\frac{E_{\text{CR}}}{10^{20} \text{ eV}} \right)^{-1} \left(\frac{B}{\mu\text{G}} \right) \times \left(\frac{L_{\text{CR}} l_{\text{cell}}}{10 \text{ Mpc} \times 0.01 \text{ Mpc}} \right)^{\frac{1}{2}} \left(\frac{\Phi_{\text{Vol}}}{0.01} \right) \quad (20)$$

This demonstrates that the propagation of UHECRs can be strongly affected by even a small filling factor of ghosts ($\Phi_{\text{Vol}} = 0.01$). The arrival directions are changed by some random angle for UHECRs above a typical energy E_* . UHECRs below this energy are isotropically scattered by ghosts, so that the length of their trajectories can be much longer than the distance to the source. For particles above the Greisen-Zatsepin-Kuzmin cutoff this can have drastic effects on the observed UHECR spectrum, since the consequent prolongation of the path reduces the flux due to the corresponding higher photo-pion energy losses (Medina-Tanco & Enßlin 1999).

4. Conclusion

Radio ghosts, patches of old, remnant, invisible radio plasma, are expected to be found frequently in the denser regions of the Universe due to the strong quasar activity at earlier epochs. Their direct detection is very difficult. But indirect methods like radio observations of re-activated electron populations in shocked ghosts seemed to have revealed them nearly 2 decades ago in the cluster radio relic phenomena. Their magnetic fields can deflect ultra high energy cosmic rays significantly in the

course of their propagation through intergalactic space. Further, the fields should trap the relativistic particle population of former radio galaxies. They should also be able to release a significant number of trapped particles under the influence of strong turbulence. The latter effect is proposed as a possible proton injection mechanism into the intra-cluster medium leading to radio halos via hadronic secondary electron and mainly positron production.

We conclude that, although the existence of ghosts is speculative, their important influence on the physics of the intergalactic medium requires further investigations.

Acknowledgements. I gratefully acknowledge many interesting discussions about the different aspects of radio ghosts with Peter Biermann, Tracy Clarke, Quentin Dufton, Phil Kronberg, and Gustavo Medina-Tanco, who invented the short term ‘ghosts’ for my ‘invisible patches of old, remnant radio plasma’.
